

Lesson 01 Summary: Python Setup

Key Concepts Review

Module 1: Python Fundamentals

What We Covered:

- Installing Anaconda and launching Jupyter Notebook
- Understanding Python's four basic data types
- Variable assignment and naming conventions
- Type conversion between different types
- Why Python beats Excel for data science

Master these fundamentals before moving forward

Four Essential Python Types

int

Whole Numbers

```
shares = 100
```

float

Decimals

```
price = 185.50
```

str

Text Strings

```
ticker = "AAPL"
```

bool

True/False

```
is_buy = True
```

Remember: `type(variable)` shows the type

int for counts, **float** for prices, **str** for tickers, **bool** for signals

Practical Applications:

- int: Number of shares, trading days, position counts
- float: Stock prices, returns, percentages
- str: Ticker symbols, company names, dates
- bool: Buy/sell signals, profitable status

Example:

```
shares = 100    # int
price = 185.50 # float
ticker = "AAPL" # str
is_buy = True  # bool
```

Choose the right type for each piece of data

Key Concept: Variable Assignment

Variable Assignment: Names Point to Values

Python Code:

```
stock_price = 185.50  
ticker = "AAPL"  
shares = 100
```

Memory:

Variable names are labels that point to values in memory

Key: Use descriptive names like `stock_price`, not `x`

Variables are names that point to values in memory

Good Names:

- `stock_price` – descriptive, uses underscore
- `daily_return` – clear purpose
- `is_profitable` – boolean prefix

Avoid:

- `x`, `temp`, `data` – too vague
- `StockPrice` – use underscores, not camelCase
- Starting with numbers: `1st_price`

Readable code uses descriptive variable names

Type Conversion (Casting)

Conversion Examples

```
int("150")      # "150" -> 150      int(150.99)    # 150.99 -> 150 (truncates!)
float("150.50") # "150.50" -> 150.5    bool(0)        # 0 -> False
str(150)        # 150 -> "150"    bool(150)     # 150 -> True
```

Convert types when reading data from files or APIs

Your Python Workflow

Jupyter = Interactive Development
Variables store values with descriptive names
Four types: int, float, str, bool

Next: Data Structures (Lists & Dictionaries)

Practice this workflow until it becomes automatic

Type Checking:

`type(variable)` – Returns the type

Type Conversion:

`int("100")` → 100

`float("3.14")` → 3.14

`str(100)` → "100"

`bool(1)` → True

F-String Formatting:

`f"Price: ${price:.2f}"` – Format with 2 decimals

Boolean Operators:

`and`, `or`, `not`, `==`, `!=`, `<`, `>`, `<=`, `>=`

Bookmark this page for quick reference

Before Next Lesson:

- 1 Complete the hands-on exercise (stock portfolio)
- 2 Practice creating variables of each type
- 3 Experiment with type conversion
- 4 Try f-string formatting with prices

Coming Up: Lesson 02 – Data Structures

Learn about lists and dictionaries for storing collections of financial data.

Practice is essential – experiment in Jupyter!
